ON THE GIBBS PHENOMENON AND ITS RESOLUTION[*]

DAVID GOTTLIEB[†] AND CHI-WANG SHU[†]

Abstract. The nonuniform convergence of the Fourier series for discontinuous functions, and in particular the oscillatory behavior of the finite sum, was already analyzed by Wilbraham in 1848. This was later named the *Gibbs phenomenon*.

This article is a review of the Gibbs phenomenon from a different perspective. The Gibbs phenomenon, as we view it, deals with the issue of recovering point values of a function from its expansion coefficients. Alternatively it can be viewed as the possibility of the recovery of local information from global information. The main theme here is not the structure of the Gibbs oscillations but the understanding and resolution of the phenomenon in a general setting.

The purpose of this article is to review the Gibbs phenomenon and to show that the knowledge of the expansion coefficients is sufficient for obtaining the point values of a piecewise smooth function, with *the same order of accuracy as in the smooth case*. This is done by using the finite expansion series to construct a different, rapidly convergent, approximation.

1. Introduction. The Gibbs phenomenon, as we view it, deals with the issue of recovering point values of a function from its expansion coefficients.

A prototype problem can be formulated as follows:

Given $2N + 1$ Fourier coefficients $\hat{f}_k$, for $-N \leq k \leq N$, of an unknown function $f(x)$ defined everywhere in $-1 \leq x \leq 1$, construct, accurately, point values of the function.

The straightforward method is to construct the classical Fourier sum:

$$(1.1) \qquad f_N(x) = \sum_{k=-N}^{N} \hat{f}_k e^{ik\pi x}.$$

This is a very good way of reconstructing the point values of $f(x)$ provided that $f(x)$ is smooth and *periodic*. In fact, if $f(x)$ is analytic and periodic, it is known that the Fourier series converges exponentially fast:

$$\max_{-1 \leq x \leq 1} |f(x) - f_N(x)| \leq e^{-\alpha N}, \qquad \alpha > 0.$$

However, if $f(x)$ is either discontinuous or nonperiodic, then $f_N(x)$ is not a good approximation to $f(x)$. In Figure 1, we present the Fourier approximation to the function $f(x) = x$ which is analytic but not periodic. It is self-evident that the quality of the convergence is poor. Two features of the approximation may be noted:

- Away from the discontinuity the convergence is rather slow. If x_0 is a fixed point in $(-1, 1)$,

$$|f(x_0) - f_N(x_0)| \sim O\left(\frac{1}{N}\right).$$

- There is an overshoot, close to the boundary, that does not diminish with increasing N; thus

$$\max_{-1 \leq x \leq 1} |f(x) - f_N(x)|$$

does not tend to zero.

The inability to recover point values of a nonperiodic, but otherwise perfectly smooth, function from its Fourier coefficients is the Gibbs phenomenon.

The Gibbs phenomenon seems to imply that it is inherently impossible to obtain accurate local information (point values) from the knowledge of global properties (Fourier coefficients) for piecewise smooth functions.

This is a far-reaching conclusion: many physical phenomena are represented by piecewise smooth functions. For example, many problems in aeronautical and space engineering involve fluid flows that contain shock waves, namely, discontinuities in the pressure field. In numerical weather prediction one has to take into account the surface of the earth, which has large gradients in the regions containing mountains. The Gibbs phenomenon seems to rule out methods based on global approximations for such problems.

Another example is data compression. It is essential to have a good representation of the data in order to decide how to compress it, namely, which information to retain. It is important to know whether the Fourier representation of the data is suitable for nonsmooth signals.

The purpose of this article is to demonstrate that the knowledge of the Fourier expansion coefficients is sufficient for obtaining the point values of a piecewise smooth function, with *the same order of accuracy as in the smooth case.*

There are two stages involved in providing information on a function: *storage and retrieval.* A good way to keep information about a function is to store its expansion coefficients; however, in the case of a discontinuous function one should use more sensitive methods to *retrieve* this information rather than naively sum up the expansion. Thus in the numerical simulations of problems involving shock waves it is meaningful to compute accurately the Fourier coefficients of the pressure function—though not to get its point values by summing up the finite Fourier series. For data compression it is also feasible to store the expansion coefficients of a function even if it is only piecewise smooth.

We have presented the Gibbs phenomenon in the case of the Fourier approximation of an analytic but nonperiodic function. However, there are many more situations in which the phenomenon manifests itself. In the following we will state a series of problems pertaining to the Gibbs phenomenon.

Problem 1. *Given* $2N + 1$ *Fourier coefficients* $\hat{f}_k$, *for* $-N \leq k \leq N$, *of an analytic but nonperiodic function* $f(x)$ *in* $-1 \leq x \leq 1$, *construct, accurately, the point values of the function.*

In Problem 1 it is assumed that the function is analytic but nonperiodic. This is equivalent to assuming that we deal with functions where the *location* of the discontinuity is known. We note that the location of the discontinuity can be obtained from its Fourier coefficients; however, it is more logical to assume that a subinterval $[a, b] \subset [-1, 1]$ is free of discontinuities. This leads us to Problem 2.

Problem 2. *Given* $2N + 1$ *Fourier coefficients* $\hat{f}_k$, *for* $-N \leq k \leq N$, *of a piecewise analytic function* $f(x)$ *in* $-1 \leq x \leq 1$, *construct, accurately, the point values of the function in any subinterval that does not include a discontinuity point.*

The Gibbs phenomenon is not limited to Fourier expansions. In fact many researchers have reported the phenomenon in many different eigenfunction expansions. Common expansions include those based on the *Chebyshev and Legendre* polynomials. Those polynomials are special cases of the *Gegenbauer polynomials.* See the Appendix for the definition.

In general, given the Gegenbauer expansion coefficients of a piecewise analytic function one faces the same convergence problems.

We pose, therefore, the following problem.

Problem 3. *Consider a piecewise analytic function $f(x)$ defined in $[-1, 1]$. Suppose that the first $0 \le k \le N$ expansion coefficients, based upon the Gegenbauer polynomials $C_k^\mu(x)$ with the weight function $(1 - x^2)^{\mu - \frac{1}{2}}$ for any constant $\mu \ge 0$, over the full interval $[-1, 1]$, are given:*

$$(1.2) \qquad \hat{f}_k^\mu = \frac{1}{h_k^\mu} \int_{-1}^1 (1 - x^2)^{\mu - \frac{1}{2}} C_k^\mu(x) f(x) dx, \qquad 0 \le k \le N.$$

Construct the point values of $f(x)$ with exponential accuracy at all points (including at the discontinuities themselves). Exponential accuracy means that the error decays as $e^{-\alpha N}$ for some $\alpha > 0$.

In Problems 1–3 we assume the knowledge of the expansion coefficients or, alternatively, the knowledge of the integrals as in (1.2). Most often these integrals are evaluated by quadrature formulas, leading to pseudospectral methods. In this context the following two problems are relevant.

Problem 4. *Let $f(x)$ be an (unknown) analytic and nonperiodic function in $-1 \le x \le 1$. Let $f(\frac{k}{N})$, $-N \le k \le N - 1$ be known. Construct, within exponential accuracy, the point values of the function everywhere.*

It is well known that constructing an interpolation polynomial at the evenly spaced collocation points yields a divergent approximation (the Runge phenomenon). Constructing a trigonometric polynomial would also not do because of the Gibbs phenomenon. The remedy will be to construct the Fourier approximation and then to treat it as a subcase of Problem 1.

The obvious extension of Problem 4 is Problem 5.

Problem 5. *Let $f(x)$ be an (unknown) piecewise analytic function in $-1 \le x \le 1$. Let $f(\frac{k}{N})$, $-N \le k \le N - 1$ be known. Construct, within exponential accuracy, the point values of the function everywhere.*

Polynomial interpolations of smooth functions converge if the collocation points are related to the zeros of orthogonal polynomials. Again, the Gibbs phenomenon occurs in the case of piecewise smooth functions. We pose therefore the following problem.

Problem 6. *Assume that the point values $f(x_i)$, where x_i are the Gauss or Gauss–Lobatto points of the orthogonal basis $\{\phi_k(x)\}$, of a discontinuous but piecewise analytic function $f(x)$, are given. Recover exponentially accurate point values over any subinterval $[a, b]$ of analyticity of $f(x)$.*

Remark 1.1. All of these problems assume piecewise analyticity. This is done in order to simplify the discussion and sharpen the results. Both the phenomenon and its resolution are valid for a piecewise smooth function having a finite number of derivatives in their domain of smoothness.

This article is a review on the Gibbs phenomenon from the perspective discussed above, i.e., the recovery of local information from the knowledge of some global information. We will not be particularly interested in the structure of the Gibbs oscil-

lations but more with the attempts to resolve the phenomenon itself, attempts that have recently led to the complete resolution of the phenomenon.

We will review the fascinating history of the discovery of the phenomenon in section 2. From our point of view the phenomenon was discovered by A. Michelson in 1898.

In section 3 we will review the use of *filters* in attempting to remove the phenomenon. This effort started with Fejér in 1900.

In section 4 we present our resolution of the Gibbs phenomenon. We demonstrate that from the knowledge of the Fourier (or Gegenbauer) expansion coefficients we can reconstruct a rapidly converging series based on other expansion functions. Thus the retrieval of the information should be done in a *different basis* than the storage of the information. The Fourier coefficients of a function contain enough information such that a *different* expansion, which is highly accurate, can be reconstructed.

2. History. A review of the Gibbs phenomenon is given in the beautiful paper by Hewitt and Hewitt [20]. They view the Gibbs phenomenon as the issue of the convergence of the partial sums of certain Fourier series in the *neighborhood* of the discontinuity; in particular they concentrate on the oscillations and the magnitude of the overshoot and undershoot. Our point of view is that the Gibbs phenomenon deals with the issue of recovering a function from a finite number of its Fourier coefficients. These two issues are related but not the same. In particular our approach raises the question of how to overcome the Gibbs phenomenon. The following historical review will be motivated by this viewpoint.

The fact that a discontinuous function can be represented as an infinite sum of sines and cosines was known already to *Euler*, who presented, in the middle of the 18th century, the following sum:

$$(2.1) \qquad \sum_{k=1}^{\infty} \frac{\sin(kx)}{k} = \frac{1}{2}(\pi - x), \qquad 0 < x < 2\pi.$$

Moreover, the nonuniform convergence of the Fourier series for discontinuous functions, and in particular the oscillatory behavior of the finite sum, was already analyzed by Wilbraham in 1848 [37]. This result was forgotten, maybe because of the context in which it appeared. Only in 1925 (see Carslaw [3]) did Wilbraham get the proper recognition for his work.

The Gibbs phenomenon, from our point of view, was first observed by Michelson. In 1898 Michelson and Stratton built a mechanical device, named a harmonic analyzer, that stored the Fourier coefficients of a given curve in its springs, using the fact that the springs obey Hooke's law. They used 80 springs but claimed that there was no limit to the number of springs that could be employed. The machine was also described in *The Encyclopedia Britannica* (1910) [6] and can be found at the Smithsonian Institute in Washington DC.

They published a paper [30] describing the machine together with some graphs of functions reconstructed from their Fourier coefficients obtained by the harmonic analyzer. The purpose of these graphs was to demonstrate that the machine computed accurately the Fourier coefficients of the functions. One of those curves was a square wave that displayed the Gibbs oscillations, but no comment was made in the paper related to the phenomenon.

Lanczos [22, p. 51] claimed that Michelson was puzzled by the fact that he could not reconstruct the square wave function and posed the problem to his friend J. Willard Gibbs. We have not been able to find evidence to support this. However, it

seems that Michelson did notice the phenomenon, since within several months of the publication of [30] he wrote a letter to the British journal *Nature* (October 6, 1898) [27] that pointed out the difficulty in constructing the function $f(x) = x$ from its Fourier coefficients. In particular, he argued that if one considered the finite Fourier approximation (1.1) $f_N(x_N)$, $x_N = \pi(1 + \frac{k}{N})$ (where k is small), then it would converge to a different value for different k's. Michelson then showed that the same problem existed with the derivative of the function.

The mathematician A.E.H. Love attacked Michelson in the next issue of *Nature* (October 13, 1898!) [24]. He started by suggesting a textbook (Hobson's "Trigonometry") to Michelson (and in fact to all other physicists bothered by nonuniform convergence) for reading. He claimed (correctly) that "the process employed is invalid." It is interesting that Love just pointed out the mathematical weakness of Michelson's argument but did not bother to understand the difficulty that Michelson had raised. It is apparent that Love was not aware of the harmonic analyzer, and he did not realize that the problem was synthesizing a function from its Fourier coefficients.

The next chapter of our story took place on December 29, 1898 in the form of three letters to the editor of *Nature*. The first one was by Michelson [28] pointing out that from his point of view convergence should be uniform at *any* neighborhood of the discontinuity. The note was dated December 1.

We now come to the name of Gibbs who was the author of the next note in the same issue (written on November 29) [9]. Gibbs explained Michelson's concerns (pointing out that Love ignored those concerns) and described the oscillations. However, he seemed to imply that the oscillations decayed with N!

Gibbs's letter was followed by another note from Love [25] expounding on the notion of nonuniform convergence and admitting "The matter...is perhaps that referred to by Prof. Michelson...but I did not understand his letter so".

Only on April 27, 1899 did Gibbs publish the correct result [10] (apologizing, "I should like to correct a careless error") and showed that the oscillations do not decay, but rather the overshoot tends to a fixed number.

The last communications appeared again in *Nature*. In May 1899 Michelson communicated a letter from Poincaré [29], and in June 1899 Love [26] basically repeated his points. Again Love was not aware that the behavior of the finite sum was crucial in reconstructing a function from its Fourier series.

The name Gibbs phenomenon was first used by Bôcher (1906) [2] who had extended the result of Gibbs.

In the 1920s the Gibbs phenomenon had been studied for expansions in other basis functions. Expansions in Bessel and Schlömlich functions were considered by Wilton [38, 39] and Cook [4, 5]. It is interesting to note that in expanding a constant function by the Fourier Bessel series one has the expected Gibbs phenomenon at $x = 1$ but also a very slow convergence that looks like the Gibbs phenomenon (but in fact is not) around $x = 0$. This was found by Gottlieb and Orszag (1977) [12] and independently by Gray and Pinsky (1993) [19] as a result of using the computer to generate the graphs of the Fourier Bessel finite series at $x = 1$. One might only speculate what form the debate on the Gibbs phenomenon would be in the age of computers!

H. Weyl [36] considered the Gibbs phenomenon for expansions in spherical harmonics, a subject most relevant nowadays since numerical weather prediction codes use expansions in spherical harmonics. For illustrations of the Gibbs phenomenon for expansions in other polynomials see [12].

The first attempt to resolve the Gibbs phenomenon was made by the Hungarian mathematician Fejér. In 1900 he discovered that the Cesàro means of the partial sums converges uniformly. This method is equivalent to first-order filters (see next section). Fejér extended this result to surface harmonics. Since then an explosion of filtering techniques, motivated by signal analysis, has occurred, the description of which is outside the scope of this limited review.

3. Filters. In this section we review the attempts to resolve the Gibbs phenomenon in the case of the Fourier expansion of a piecewise smooth function (see Problem 2 in the introduction). Methods to resolve the Gibbs phenomenon fall into one of two classes. The first class contains those methods that treat the approximation in the Fourier space, by modifying the expansion coefficients. In the second class we consider methods that treat the approximation in the physical space.

Both classes of methods are successful in enhancing the accuracy but only *away from the discontinuity.*

Consider the Fourier–Galerkin projection of a piecewise smooth function $f(x)$, $0 \leq x \leq 2\pi$ (note that in this section we use the interval $[0, 2\pi]$ instead of $[-1, 1]$):

$$(3.1) \qquad f_N(x) = \sum_{k=-N}^{N} \hat{f}_k e^{ikx},$$

where the coefficients $\hat{f}_k$ are given by

$$(3.2) \qquad \hat{f}_k = \frac{1}{2\pi} \int_0^{2\pi} f(x) e^{-ikx} dx.$$

The reason for the slow (and nonuniform) convergence of $f_N(x)$ to $f(x)$ can be traced to two facts:

- the slow decay of the Fourier coefficients $\hat{f}_k$;
- the global nature of the Fourier series, where the Fourier coefficients are determined by integration over the *whole interval* (see (3.2)), even across discontinuities.

These are two different manifestations of the same phenomenon and not two independent causes of it. However, in attempting to resolve the Gibbs phenomenon, two different approaches have been taken; each approach treats a different aspect of the phenomenon.

3.1. Fourier space filters. In this subsection we will review efforts to resolve the Gibbs phenomenon by *enhancing the decay rate of the given Fourier coefficients without reducing the accuracy.*

Assume that we are given the first $2N+1$ Fourier coefficient of a piecewise smooth (C^q or analytic) function $f(x)$ with a discontinuity point $x = \xi$. We would like to recover the value $f(y)$, $0 \leq y \leq 2\pi$, by multiplying the Fourier coefficients by the factors $\sigma\left(\frac{k}{N}\right)$ such that the modified sum

$$(3.3) \qquad f_N^{\sigma}(y) = \sum_{k=-N}^{N} \hat{f}_k \sigma\left(\frac{k}{N}\right) e^{iky}$$

converges *faster* than the original sum

$$(3.4) \qquad f_N(y) = \sum_{k=-N}^{N} \hat{f}_k e^{iky}.$$

Note that we can rewrite (3.3) as a convolution in the *physical space*:

$$(3.5) \qquad f_N^\sigma(y) = \frac{1}{2\pi} \int_0^{2\pi} S(y-t) f_N(t) dt,$$

where the *filter function* $S(x)$ (which depends on N) is the representation of the filter $\sigma\left(\frac{k}{N}\right)$ in the physical space; namely,

$$(3.6) \qquad S(x) = \sum_{k=-N}^{N} \sigma\left(\frac{k}{N}\right) e^{ikx}, \qquad 0 \le x \le 2\pi.$$

The definition of a filter characterizes the behavior of $\sigma(\eta)$ as a function of its argument. We will follow here the presentation by Vandeven [33].

DEFINITION 3.1 (the Fourier space filter of order p). *A real and even function $\sigma(\eta)$ is called a* filter of order p *if*
 (a) $\sigma(0) = 1$, $\sigma^{(l)}(0) = 0$, $\quad 1 \le l \le p-1$.
 (b) $\sigma(\eta) = 0$, $\quad |\eta| \ge 1$.
 (c) $\sigma(\eta) \in C^{p-1}$, $\quad \eta \in (-\infty, \infty)$.
Remarks.
  1. The filter does not modify the low modes but only the high ones. Note that because of conditions (b) and (c),

$$\sigma^{(l)}(1) = 0, \qquad 0 \le l \le p-1.$$

However, just zeroing out high modes is not enough. It is *essential* that the filter function $\sigma(\eta)$ is a smooth function of η. It is well known to practitioners that cutting high modes and leaving the rest unchanged (namely, using $\sigma(\eta) = 1$ for $|\eta| \le \eta_0$ and $\sigma(\eta) = 0$ for $|\eta| > \eta_0$) will not improve the convergence, since this will only give the original sum with fewer number of terms.
  2. If $f(x)$ is a C^{p-1} periodic function, then multiplying its Fourier coefficients by a filter that satisfies condition (a) does not change the order of accuracy. It is the other two conditions, (b) and (c), that become important when $f(x)$ is only piecewise smooth.
  3. Condition (b) assures that we can extend the finite sum in (3.3) to an infinite series:

$$(3.7) \qquad f_N^\sigma(y) = \sum_{k=-\infty}^{\infty} \hat{f}_k \sigma\left(\frac{k}{N}\right) e^{iky}.$$

And, consequently, instead of (3.5) we have a convolution with $f(t)$ itself:

$$(3.8) \qquad f_N^\sigma(y) = \frac{1}{2\pi} \int_0^{2\pi} S(y-t) f(t) dt.$$

The function $f(x)$ appears in the right side of (3.8), rather than its finite Fourier sum $f_N(x)$ as in (3.5). The effect of *truncating* the infinite Fourier sum of $f(x)$ is eliminated. We loosely define the term *truncation error* as

$$TE_N(y) = \sum_{k=-\infty}^{\infty} \hat{f}_k \sigma\left(\frac{k}{N}\right) e^{iky} - \sum_{k=-N}^{N} \hat{f}_k \sigma\left(\frac{k}{N}\right) e^{iky}.$$

In this case, with the conditions (b) and (c), this error $TE_N(y)$ will vanish. The concept of truncation error will again appear later in this section and the next section. Truncation errors are manifestations of the weak convergence of the Fourier partial sum $f_N(x)$ to $f(x)$.

4. It will be shown that conditions (b) and (c) together assure that the filter function $S(x)$ and its integrals decay in N for any fixed x, $0 < x < 2\pi$.

Of major importance in the analysis are the *integrals* of the filter function $S(x)$ defined in (3.6).

DEFINITION 3.2. *Let $S(x)$ be defined in (3.6); then its integrals $S_l(x)$ are defined by*

$$(3.9) \qquad S_0(x) = S(x),$$

$$(3.10) \qquad S_l^{'}(x) = S_{l-1}(x), \qquad l \geq 1,$$

$$(3.11) \qquad \int_0^{2\pi} S_l(t)dt = 0, \qquad l \geq 1,$$

and extended periodically outside $(0, 2\pi)$.

The functions $S_l(x)$ have several alternative representations. Some are given in Lemma 3.1.

LEMMA 3.1. *Assume that σ is a filter of order p according to Definition 3.1. The functions $S_l(x)$, defined in (3.6), (3.9)–(3.11), for $0 \leq x \leq 2\pi$, have the following equivalent representations:*

$$(3.12) \qquad S_l(x) = N^{-l} \sum_{k=-\infty}^{\infty} G_l\left(\frac{k}{N}\right) \frac{1}{i^l} e^{ikx}, \qquad 1 \leq l \leq p,$$

where

$$(3.13) \qquad G_l(\eta) = \frac{\sigma(\eta) - 1}{\eta^l}.$$

$$(3.14) \qquad S_l(x) = N^{1-l} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} e^{iN(x+2m\pi)\eta} G_l(\eta) i^{-l} d\eta, \qquad 1 \leq l \leq p.$$

$$(3.15) \qquad S_0(x) = 1 + \sum_{k \neq 0} \sigma\left(\frac{k}{N}\right) e^{ikx},$$

$$(3.16) \qquad S_1(x) = x - \pi + \sum_{k \neq 0} \sigma\left(\frac{k}{N}\right) \frac{1}{ik} e^{ikx},$$

$$(3.17) \qquad S_l(x) = B_l(x) + \sum_{k \neq 0} \sigma\left(\frac{k}{N}\right) \frac{1}{(ik)^l} e^{ikx}, \qquad l \geq 2,$$

where $B_l(x)$ are the Bernoulli polynomials of degree l. □

The importance of the integrals $S_l(x)$ of the filter function $S(x)$ becomes evident if we integrate the right side of equation (3.8) by parts, taking care not to cross the point of discontinuity ξ. We get Theorem 3.1.

THEOREM 3.1. *Let $f(x)$ be a piecewise C^p function with one point of discontinuity ξ. Then*

$$(3.18) \qquad \begin{aligned} f_N^\sigma(y) &= f(y) + \frac{1}{2\pi} \sum_{l=0}^{p-1} S_{l+1}(c) \left(f^{(l)}(\xi^+) - f^{(l)}(\xi^-) \right) \\ &\quad + \frac{1}{2\pi} \int_0^{2\pi} S_p(y - t) f^{(p)}(t)dt, \end{aligned}$$

where c is either $y - \xi$ (if $y > \xi$) or $2\pi + y - \xi$ (if $y < \xi$). Here and below the integration $\int_0^{2\pi}$ is understood to be the sum $\int_0^\xi + \int_\xi^{2\pi}$; i.e., the singularity of $f^{(p)}(t)$ at $t = \xi$ is not considered in the integration. □

Theorem 3.1 provides the precise error between the (unknown) point value $f(y)$ and the filtered sum $f_N^\sigma(y)$. The last two terms in the right-hand side of (3.18) can be estimated from the properties of the filter.

Note first that if $f(x)$ is a C^{p-1} function then the first term in the right-hand side of (3.18) vanishes and we are left only with the second term. Thus it is really the error term for *smooth functions*. We estimate this term with the use of condition (a) in the definition of the filter.

LEMMA 3.2. *Let $S_l(x)$ be defined by (3.9)–(3.11); then*

$$(3.19) \qquad \frac{1}{2\pi}\left|\int_0^{2\pi} S_p(y-t)f^{(p)}(t)dt\right| \le CN^{\frac{1}{2}-p}\left(\int_0^{2\pi}|f^{(p)}(t)|^2 dt\right)^{\frac{1}{2}},$$

where C is a constant independent of f or N.

Proof. We begin by noting that by a standard application of the Cauchy–Schwarz inequality and the periodicity of $S_p(t)$,

$$(3.20) \qquad \left|\int_0^{2\pi} S_p(y-t)f^{(p)}(t)dt\right| \le \left(\int_0^{2\pi}S_p^2(t)dt\right)^{\frac{1}{2}}\left(\int_0^{2\pi}|f^{(p)}(t)|^2\right)^{\frac{1}{2}}.$$

Using the representation of $S_l(x)$ given in Lemma 3.1 (3.12) we get

$$\frac{1}{2\pi}\int_0^{2\pi}S_p^2(t)dt = \sum_{k=-\infty}^{\infty}\left(\frac{\sigma\left(\frac{k}{N}\right)-1}{k^p}\right)^2$$

$$(3.21) \qquad = N^{1-2p}\sum_{k=-N}^{N}\left(\frac{\sigma\left(\frac{k}{N}\right)-1}{(\frac{k}{N})^p}\right)^2\frac{1}{N} + \sum_{|k|>N}\frac{1}{k^{2p}}.$$

The first term on the right side of (3.21) is N^{1-2p} times the Riemann sum of the integral

$$\int_{-1}^{1}G_p^2(\eta)d\eta = \int_{-1}^{1}\left(\frac{\sigma(\eta)-1}{\eta^p}\right)^2 d\eta,$$

which is bounded because of condition (a) in Definition 3.1 of the filter. The second term on the right-hand side of (3.21) is bounded by the same power of N.

Thus,

$$(3.22) \qquad \left(\int_0^{2\pi}S_p^2(t)dt\right)^{\frac{1}{2}} \le CN^{\frac{1}{2}-p}\int_{-1}^{1}\left(\frac{\sigma(\eta)-1}{\eta^p}\right)^2 d\eta.$$

Substituting (3.22) into (3.20) proves (3.19) with the constant C proportional to $\int_{-1}^{1}(\frac{\sigma(\eta)-1}{\eta^p})^2 d\eta$. ☐

We go back now to equation (3.18) and treat the terms $S_l(c)$. We will show that condition (b) and (c) of the filter implies that these terms are small. For that we use representation (3.14) to shuttle between the physical space and the Fourier space.

THEOREM 3.2. *Let $S_l(x)$, $l \ge 1$, be given in (3.9)–(3.11); then for $0 < x < 2\pi$,*

$$(3.23) \quad |S_l(x)| \le A\frac{1}{N^{p-1}}\left(\frac{1}{|x|^{p-l}} + \frac{1}{|2\pi-x|^{p-l}}\right)\int_{-\infty}^{\infty}|G_l^{(p-l)}(\eta)|d\eta, \qquad 1 \le l \le p.$$

Proof. We begin with (3.14) and integrate by parts $(p - l)$ times. Since the function $G_l(\eta)$ is a C^{p-1} function from the definition of the filter (in fact this is exactly the reason why $\sigma(1)$ has to vanish with its derivatives), we have

$$(3.24) \qquad |S_l(x)| = N^{1-l} \left| \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{e^{iN(x+2m\pi)\eta}}{N^{p-l}(x + 2m\pi)^{p-l}} G_l^{(p-l)}(\eta) d\eta \right|.$$

The significant terms for m are $m = 0, -1$, leading to (3.23). □

We can now summarize the following result.

THEOREM 3.3. *Let $f(x)$ be a piecewise C^p function with one point of discontinuity ξ. Let $\sigma\left(\frac{k}{N}\right)$ be a filter of order p satisfying Definition 3.1. Let now y be a point in $[0, 2\pi]$ and denote by $d(y) = \min_{k=-1,0,1} |y - \xi + 2k\pi|$. Let*

$$(3.25) \qquad f_N^\sigma(y) = \sum_{k=-\infty}^{\infty} \hat{f}_k \sigma\left(\frac{k}{N}\right) e^{iky}.$$

Then

$$(3.26) \qquad |f(y) - f_N^\sigma(y)| \leq CN^{1-p} d(y)^{1-p} K(f) + CN^{\frac{1}{2}-p} \|f^{(p)}\|_{L^2},$$

where

$$(3.27) \qquad K(f) = \sum_{l=0}^{p-1} d(y)^l \left(f^{(l)}(\xi^+) - f^{(l)}(\xi^-) \right) \int_{-\infty}^{\infty} |G_l^{(p-l)}(\eta)| d\eta.$$

Proof. From Theorem 3.1 we get

$$(3.28) \qquad \begin{aligned} f_N^\sigma(y) - f(y) &= \frac{1}{2\pi} \sum_{l=0}^{p-1} S_{l+1}(c) \left(f^{(l)}(\xi^+) - f^{(l)}(\xi^-) \right) \\ &\quad + \frac{1}{2\pi} \int_0^{2\pi} S_p(y - t) f^{(p)}(t) dt. \end{aligned}$$

The last term in (3.28) is bounded by Lemma 3.2:

$$(3.29) \qquad \frac{1}{2\pi} \left| \int_0^{2\pi} S_p(y - t) f^{(p)}(t) dt \right| \leq CN^{\frac{1}{2}-p} \left(\int_0^{2\pi} |f^{(p)}(t)|^2 dt \right)^{\frac{1}{2}}.$$

The first term in (3.28) is bounded by Theorem 3.2. Note that $c = y - \xi$ if $y > \xi$ and $c = 2\pi + y - \xi$ if $y < \xi$ and, therefore,

$$(3.30) \qquad \frac{1}{c^{p-l}} + \frac{1}{|2\pi - c|^{p-l}} \leq \frac{2}{d^{p-l}}.$$

Combining (3.23), (3.29), and (3.30) yields the theorem. □

The theorem demonstrates that the filtering process works *away from the discontinuity*, since all the terms on the right-hand side of (3.18) can be made $O(N^{1-p})$. Thus the pth order of accuracy can be achieved even for piecewise smooth functions.

Theorem 3.3 can be cast in a different way as was suggested by Vandeven [33].

THEOREM 3.4. *We have*

$$(3.31) \qquad |f(y) - f_N^\sigma(y)| \leq AN^{1-p} d(y)^{1-p} \||f\||_p,$$

where $\||f\||_p$ is the local Sobolev p-norm, that is, the sum of the Sobolev p-norms in each interval of smoothness. □

There are many examples of filters that have been used during the years. We would like to mention some of them.

1. In 1900 Fejér suggested using averaged partial sums instead of the original sums. This is equivalent to the first-order filter

$$\sigma_1(\eta) = 1 - \eta.$$

2. The Lanczos filter is formally a first-order filter

$$\sigma_2(\eta) = \frac{\sin(\pi\eta)}{\pi\eta}.$$

However, note that at $\eta = 0$, it satisfies the condition for a second-order filter.

3. A second-order filter is the *raised cosine* filter

$$\sigma_3(\eta) = \frac{1}{2}\left(1 + \cos(\pi\eta)\right).$$

4. The sharpened raised cosine filter is given by

$$\sigma_4(\eta) = \sigma_3^4(\eta)(35 - 84\sigma_3(\eta) + 70\sigma_3^2(\eta) - 20\sigma_3^3(\eta)).$$

This is an *eighth-order filter*.

5. The exponential filter of order p (for even p) is given by

$$\sigma_5(\eta) = e^{-\alpha\eta^p}.$$

Note that formally the exponential filter does not conform to the definition of the filter as $\sigma_5(1) = e^{-\alpha}$. Thus the truncation error does not vanish. In practice we choose α such that $e^{-\alpha}$ is within the roundoff error of the specific computer.

6. Vandeven [33] suggested a filter of order p that minimizes the constant A in the right side of (3.31):

$$(3.32) \qquad \sigma_6(\eta) = 1 - \frac{(2p-1)!}{(p-1)!^2}\int_0^\eta [t(1-t)]^{p-1}dt.$$

This is essentially the Daubechies filter leading to wavelets [32].

What about piecewise analytic functions?

It has been shown by Vandeven [33] that if we allow the order p of the filter $\sigma_6(\eta)$ to grow with the number of known coefficients N, then an exponential accuracy can be recovered *away from the discontinuity*.

We close this section by noting that there is no additional computational cost in applying the Fourier space filters. Constructing either the Fourier partial sum or the filtered sum can be done in $N\log(N)$ operations.

3.2. Filters in physical space. The second approach to overcome the Gibbs phenomenon is based on trying to localize the information that determines the Fourier coefficients $\hat{f}_k$.

Denote again by

$$(3.33) \qquad f_N(x) = \sum_{k=-N}^{N} \hat{f}_k e^{ikx}.$$

We look for a function $\Psi(y,t)$ such that

$$(3.34) \qquad \int_0^{2\pi} f_N(t)\Psi(y,t)dt \sim f(y).$$

Note that if $\Psi(y,t) = \Psi(y-t)$ we get back the formulation (3.5). Now, though, the truncation error does not vanish. In fact,

$$(3.35) \quad \int_0^{2\pi} f_N(t)\Psi(y,t)dt = f(y) + \left(\int_0^{2\pi} f(t)\Psi(y,t)dt - f(y) \right)$$

$$(3.36) \quad\quad\quad\quad + \left(\int_0^{2\pi} f_N(t)\Psi(y,t)dt - \int_0^{2\pi} f(t)\Psi(y,t)dt \right).$$

We recall now the concept of truncation error (see section 3.1).

DEFINITION 3.3. *The* truncation error $T_e(y)$ *is defined as (see (3.36))*.

$$(3.37) \quad\quad T_e(y) = \left| \int_0^{2\pi} f_N(t)\Psi(y,t)dt - \int_0^{2\pi} f(t)\Psi(y,t)dt \right|.$$

The regularization error $R_e(y)$ is the second term in the right-hand side of (3.35)

$$(3.38) \quad\quad R_e(y) = \left| \int_0^{2\pi} f(t)\Psi(y,t)dt - f(y) \right|.$$

Our aim is to find $\Psi(y,t)$ such that both the truncation and regularization errors are small. We start with the estimation of the truncation error.

LEMMA 3.3. *Let the truncation error be defined in* (3.37). *Then*

$$(3.39) \quad\quad T_e(y) \le CN^{-p}||\Psi^{(p)}||_{L^2}.$$

Proof. We start with

$$(3.40) \quad T_e(y) = \left| \int_0^{2\pi} (f(t) - f_N(t))\,\Psi(y,t)dt \right|$$

$$(3.41) \quad\quad = \left| \int_0^{2\pi} (f(t) - f_N(t))\,(\Psi(y,t) - \Psi_N(y,t))\,dt \right|$$

$$(3.42) \quad\quad \le \left(\int_0^{2\pi} (f(t) - f_N(t))^2 dt \right)^{\frac{1}{2}} \left(\int_0^{2\pi} (\Psi(y,t) - \Psi_N(y,t))^2 dt \right)^{\frac{1}{2}}$$

$$(3.43) \quad\quad \le CN^{-p}||\Psi^{(p)}||_{L^2},$$

where $\Psi_N(y,t)$ is the partial Fourier sum of $\Psi(y,t)$ with respect to the variable t. (3.41) follows from the fact that $\Psi_N(y,t)$ is orthogonal to any polynomials with degree greater than N. (3.43) is a direct application of the approximation theory for smooth functions. □

We assume now that $f(x)$ is a C^p function in a symmetric interval around y, say, $[y - \epsilon, y + \epsilon]$. Define

$$\xi = \frac{x - y}{\epsilon}.$$

In [18] the following filter function Ψ was suggested:

$$\Psi(y,x) = \rho(\xi(x))\frac{1}{2\epsilon} \sum_{k=-m}^{m} e^{\pi i k \xi(x)},$$

$$\rho(\xi(x)) \in C^p[-\infty, \infty],$$

$$\rho(0) = 1, \quad \text{and} \quad \rho(\xi(x)) = 0, \quad |\xi| > 1.$$

Note that the function ρ is a localizer whereas $\frac{1}{2\epsilon}\sum_{k=-m}^{m}e^{\pi i k \xi(x)}$ is an approximation to the δ function.

The rationale behind this choice is clear when one looks at the regularization error:

$$\int_0^{2\pi} f(t)\Psi(y,t)dt = \frac{1}{2\epsilon}\int_{y-\epsilon}^{y+\epsilon} f(t)\rho\left(\frac{t-y}{\epsilon}\right)\sum_{k=-m}^{m}e^{\pi i k \xi(t)}dt$$

(3.44)

$$= \frac{1}{2}\int_{-1}^{1} f(y+\epsilon\xi)\rho(\xi)\sum_{k=-m}^{m}e^{\pi i k \xi}d\xi.$$

Note that the function

$$f(y+\epsilon\xi)\rho(\xi)$$

is C^p for $-1 \le \xi \le 1$, and, when extended periodically, if we denote its Fourier coefficients by $\hat{g}_k$, we get that

(3.45) $$\int_0^{2\pi} f(t)\Psi(y,t)dt = \sum_{k=-m}^{m}\hat{g}_k e^{\pi i k} = f(y) + R(y),$$

where $R(y)$ is the tail of the Fourier series for the periodic smooth function $f(y+\epsilon\xi)\rho(\xi)$, and thus tends quickly to zero with m.

In [18] these arguments were quantified. We quote the following theorem.

THEOREM 3.5. *Let* $m = \frac{1}{2}N$; *then*

$$\left|\int_0^{2\pi} f_N(t)\Psi(y,t) - f(y)\right|$$

$$\le N^{-\frac{s}{2}}\left(C_s\|R\|_s N^{1.5}\|f_N - f\|_{L^1}\epsilon^{-s} + \max_{0\le k \le s}\max_{|y-x|\le\epsilon\pi}|D^k f(x)|\right). \qquad \square$$

We should note that no attempt to optimize the filter had been made.

We close this section with the following remarks.

1. We can replace $e^{\pi i k \xi}$ by the *Legendre polynomials* $P_k(\xi)$ (see [11]).
2. The computational cost here is significantly higher than in the case of the Fourier space filters. However, if one decides beforehand on a distance ϵ from the discontinuity, then the filter is of convolution type and can be computed efficiently.
3. One can view (3.44) as multiplying $f(x)$ by a localizer around y and then expanding the new function in an orthogonal expansion in the subinterval $[y-\epsilon, y+\epsilon]$. Note that the approximation deteriorates as $\epsilon \to 0$. The fact that the interval is symmetric implies that with this approach we cannot recover the accuracy close to the discontinuity.

4. The resolution of Gibbs phenomenon. In this section we describe recent work on the resolution of the Gibbs phenomenon [13], [14], [15], [16], [17], [7]. In these papers we outlined a procedure to remove the Gibbs phenomenon completely, i.e., to obtain exponential accuracy in the maximum norm in any interval of analyticity, based on the Fourier or Gegenbauer series of a discontinuous but piecewise analytic function.

We revisit Problem 1 to explain the methodology employed; i.e., we assume the knowledge of the first $2N + 1$ Fourier coefficients of an analytic but nonperiodic function.

This procedure utilizes the Gegenbauer polynomials $C_k^\lambda(x)$, which are orthogonal over the range $x \in [-1, 1]$ with the weight function $(1 - x^2)^{\lambda - \frac{1}{2}}$ for *large* $\lambda \sim N$. See the Appendix for definitions and properties of Gegenbauer polynomials. The Gegenbauer polynomials arise naturally when we try to generalize the physical space filter (3.34) to nonsymmetric intervals. In fact we have shown in section 3.2 that the truncation error is small if Φ, viewed as a periodic function, is smooth (3.39), while the regularization error is small if Ψ approximates a δ-function (3.45). It is therefore natural to choose Ψ as a product of $w(x) = (1 - x^2)^\mu$ for a large μ and a δ-function based on the inner product with the weight $w(x)$. This leads to the Gegenbauer polynomials.

The proof of exponential convergence involves showing that the error committed by expanding the Nth Fourier coefficient into Gegenbauer polynomials can be made exponentially small. Calling f_N^m the expansion of f_N into mth-degree Gegenbauer polynomials and f^m the expansion of $f(x)$ into mth-degree Gegenbauer polynomials, one proves that the error

$$||f - f_N^m|| \le ||f - f^m|| + ||f^m - f_N^m||$$

can be made exponentially small by showing this for each term separately, where the norm is the maximum norm over $[-1, 1]$. The first term is the *regularization error*, while the second term is the *truncation error*.

The suggested procedure thus consists of the following two steps.

Step one. Compute the first $m + 1$ Gegenbauer coefficients of $f_N(x)$:

$$\hat{g}_k^\lambda = \frac{1}{h_k^\lambda} \int_{-1}^1 (1 - x^2)^{\lambda - \frac{1}{2}} f_N(x) C_k^\lambda(x) dx, \ \ 0 \le k \le m,$$

where h_k^λ are normalization constants. The *truncation error* is

(4.1)
$$||f^m - f_N^m|| = \max_{-1 \le x \le 1} \left| \sum_{k=0}^m \left(\hat{f}_k^\lambda - \hat{g}_k^\lambda \right) C_k^\lambda(x) \right|,$$

where $\hat{f}_k^\lambda$ are the (unknown) Gegenbauer coefficients of the original function $f(x)$. It can be proven that this truncation error is exponentially small if *both λ and m grow linearly with N*.

Step two. Construct the Gegenbauer series

$$\sum_{k=0}^m \hat{g}_k^\lambda C_k^\lambda(x) \sim \sum_{k=0}^m \hat{f}_k^\lambda C_k^\lambda(x) = f^m(x),$$

where λ is proportional to m. The error incurred at this stage is labeled *regularization error*:

$$||f - f^m|| = \max_{-1 \le x \le 1} \left| f(x) - \sum_{k=0}^m \hat{f}_k^\lambda C_k^\lambda(x) \right|.$$

It can be proven that this regularization error is again exponentially small for the choice $\lambda = \gamma m$ with any positive constant γ.

The combination of the two steps gives us the procedure to obtain an exponentially convergent approximation in the maximum norm over the whole interval $[-1, 1]$.

The idea presented above can be generalized to solve all the problems presented in the introduction. The first N expansion coefficients (or the value of the function in N appropriate collocation points) provide enough information to construct accurately the first m Gegenbauer expansion coefficients based on a subinterval $[a, b]$ in which the function is smooth.

In the first subsection we consider the truncation errors corresponding to the problems raised in the introduction. The second subsection is devoted to the estimation of the regularization error. In the last subsection we show how the previous subsections lead to the elimination of the Gibbs phenomenon.

4.1. The truncation error. In this subsection we consider the truncation error. We assume we are given a spectral partial sum of an arbitrary L_1 function $f(x)$ defined in $[-1, 1]$:

$$(4.2) \qquad f_N(x) = \sum_{k=0}^{N} \hat{f}_k \phi_k(x),$$

where $\phi_k(x)$ could be the trigonometric function $e^{2\pi k i x}$ (where the summation in (4.2) runs from $-N$ to N), or the general Gegenbauer function $C_k^\mu(x)$ including the Legendre $\mu = \frac{1}{2}$ and Chebyshev $\mu = 0$ as special cases. The spectral coefficients $\hat{f}_k$ could be from either a Galerkin expansion or a collocation (pseudospectral) expansion.

We are interested in getting an exponentially accurate approximation to the Gegenbauer expansion of $f(x)$ over a subinterval $[a, b] \subset [-1, 1]$ (which could be $[-1, 1]$ itself or a true subinterval), based on the given spectral partial sum $f_N(x)$ in (4.2). If $f(x)$ contains any discontinuity, this is typically not possible if the parameter λ in the Gegenbauer expansion is *fixed*. However, it is possible if we choose $\lambda \sim N$.

For the Galerkin cases an L_1 assumption on $f(x)$ is enough for this subsection. For the collocation cases additional smoothness of $f(x)$ in the subinterval $[a, b]$ is needed:

$$(4.3) \qquad \max_{a \leq x \leq b} \left| \frac{d^k f}{dx^k}(x) \right| \leq C(\rho) \frac{k!}{\rho^k} \qquad \text{for all } k \geq 0.$$

This is a standard assumption for analytic functions; $\rho > 0$ is actually the distance from $[-1, 1]$ to the nearest singularity of $f(x)$ in the complex plane (see, for example, [21]).

We define the local variable ξ by $\xi = \xi(x) = \frac{x - \delta}{\epsilon}$, or $x = x(\xi) = \epsilon \xi + \delta$, with $\epsilon = \frac{b-a}{2}$, $\delta = \frac{b+a}{2}$. Thus $-1 \leq \xi \leq 1$ corresponds to $a \leq x \leq b$. The L_1 function $f(x)$ has a Gegenbauer expansion in the subinterval $[a, b]$:

$$(4.4) \qquad f(\epsilon \xi + \delta) = \sum_{l=0}^{\infty} \hat{f}_\epsilon^\lambda(l) C_l^\lambda(\xi), \qquad -1 \leq \xi \leq 1,$$

where the Gegenbauer coefficients $\hat{f}_\epsilon^\lambda(l)$ are defined by

$$(4.5) \qquad \hat{f}_\epsilon^\lambda(l) = \frac{1}{h_l^\lambda} \int_{-1}^{1} (1 - \xi^2)^{\lambda - \frac{1}{2}} C_l^\lambda(\xi) f(\epsilon \xi + \delta) d\xi.$$

See the Appendix for the definition of h_l^λ.

Of course, we do not know the function $f(x)$ itself but just its spectral partial sum $f_N(x)$. Therefore, we have at our disposal only an approximation $\hat{g}_\epsilon^\lambda(l)$, based on $f_N(x)$, to the true Gegenbauer coefficients $\hat{f}_\epsilon^\lambda(l)$ defined in (4.5). For the Galerkin case, this approximation is given by

$$(4.6) \qquad \hat{g}_\epsilon^\lambda(l) = \frac{1}{h_l^\lambda} \int_{-1}^{1} (1 - \xi^2)^{\lambda - \frac{1}{2}} C_l^\lambda(\xi) f_N(\epsilon\xi + \delta) d\xi.$$

For the collocation case, we have difficulty in proving exponential accuracy if (4.6) is used. Instead, we incorporate the weight function into $f(x)$ before collocation. We thus define

$$(4.7) \qquad g_N(x) = I_N\left(\alpha \cdot f\right)(x),$$

where I_N is the collocation operator, and $\alpha(x)$ is the weight function defined by

$$(4.8) \qquad \alpha(x) = \begin{cases} (1 - \xi(x)^2)^{\lambda - \frac{1}{2}}, & a \leq x \leq b, \\ 0 & \text{otherwise.} \end{cases}$$

This works for the case $\int_{-1}^{1} \frac{1}{w(x)} dx < \infty$, where $w(x)$ is the weight function of the basis $\{\phi_k\}$. Most commonly used bases belong to this class, for example, the Fourier case where $w(x) = 1$ and the Gegenbauer case where $w(x) = (1-x^2)^{\mu - \frac{1}{2}}$, when $\mu < \frac{3}{2}$, which includes Chebyshev and Legendre cases. If the weight function is not inversely integrable, a slightly different definition for $g_N(x)$ is needed (see [17] for details). The approximation $\hat{g}_\epsilon^\lambda(l)$ is then given by

$$(4.9) \qquad \hat{g}_\epsilon^\lambda(l) = \frac{1}{h_l^\lambda} \int_{-1}^{1} g_N(\epsilon\xi + \delta) C_l^\lambda(\xi) d\xi.$$

We now formally define the truncation error.

DEFINITION 4.1. *The truncation error is defined by*

$$(4.10) \qquad TE(\lambda, m, N, \epsilon) = \max_{-1 \leq \xi \leq 1} \left| \sum_{l=0}^{m} (\hat{f}_\epsilon^\lambda(l) - \hat{g}_\epsilon^\lambda(l)) C_l^\lambda(\xi) \right|,$$

where $\hat{f}_\epsilon^\lambda(l)$ are defined by (4.5) and $\hat{g}_\epsilon^\lambda(l)$ are defined by (4.6) for the Galerkin case and by (4.9) for the collocation case. □

The truncation error is the measure of the distance between the true Gegenbauer expansion of $f(x)$ in the interval $[a, b]$ and its approximation based on the spectral partial sum. We can summarize the estimates of truncation errors under different situations [13, 15, 16, 17, 7] in Theorem 4.1.

THEOREM 4.1. *Let the truncation error be defined by (4.10). Let $\lambda = \alpha\epsilon N$ and $m = \beta\epsilon N$ with α, β constants; then*

$$(4.11) \qquad TE(\alpha\epsilon N, \beta\epsilon N, N, \epsilon) \leq A q_T^{\epsilon N},$$

where A grows at most as a fixed-degree polynomial of N, and q_T is given by the following:

(i) For the Galerkin expansion in Fourier spectral series [13, 15],

$$(4.12) \qquad q_T = \frac{(\beta + 2\alpha)^{\beta + 2\alpha}}{(2\pi e)^\alpha \alpha^\alpha \beta^\beta}.$$

In particular, if $\alpha = \beta < \frac{2\pi e}{27}$ then $q_T < 1$.

(ii) *For the Galerkin expansion in general Gegenbauer series (this includes Cheby-shev and Legendre)* [16],

$$(4.13) \qquad q_T = \frac{(\beta + 2\alpha)^{\beta+2\alpha}}{2^\alpha \alpha^\alpha \beta^\beta}.$$

In particular, if $\alpha = \beta < \frac{2}{27}$ then $q_T < 1$.

(iii) *For the collocation expansion in Fourier or general Gegenbauer spectral series* [17],

$$(4.14) \qquad q_T = \frac{(\beta + 2\alpha)^{\beta+2\alpha}}{e^\alpha \alpha^\alpha \beta^\beta} \cdot \left(\frac{1}{2} + \frac{1}{4\rho} \right)^\alpha,$$

where ρ is given by (4.3). In particular, if $\alpha = \beta < \frac{2e}{27\left(1 + \frac{1}{2\rho}\right)}$, then $q_T < 1$.

(iv) *For the spherical harmonic expansion* [7],

$$(4.15) \qquad q_T = \frac{(\beta + 2\alpha)^{\beta+2\alpha}}{2^\alpha \alpha^\alpha \beta^\beta}.$$

In particular, if $\alpha = \beta < \frac{2}{27}$, then $q_T < 1$. □

We note that for the Galerkin case, the estimate for the general Gegenbauer expansions is less sharp (missing a factor of $\frac{1}{\pi e}$) than that of the Fourier expansion. This is perhaps due to the different methods of proof. For the special case of Legendre expansion among general Gegenbauer expansions, sharper results similar to that for the Fourier case can be obtained [15].

We now describe some key ideas in the proof of Theorem 4.1. For the Galerkin case, by (4.2), (4.4), (4.5), and (4.6), the truncation error (4.10) can be expressed as

$$TE(\lambda, m, N, \epsilon) = \max_{-1 \le \eta \le 1} \left| \sum_{l=0}^{m} \frac{C_l^\lambda(\eta)}{h_l^\lambda} \int_{-1}^{1} (1 - \xi^2)^{\lambda - \frac{1}{2}} C_l^\lambda(\xi) \sum_{k=N+1}^{\infty} \hat{f}_k \phi_k(\epsilon \xi + \delta) \, d\xi \right|$$

$$\le A \sum_{l=0}^{m} \sum_{k=N+1}^{\infty} \frac{C_l^\lambda(1)}{h_l^\lambda} \left| \int_{-1}^{1} (1 - \xi^2)^{\lambda - \frac{1}{2}} C_l^\lambda(\xi) \phi_k(\epsilon \xi + \delta) \, d\xi \right|.$$

We have used (6.5) from the Appendix and the fact that $f(x)$ is in L_1; hence, $|\hat{f}_k| \le A$. Now, the first sum in l will only give a factor of $m \sim N$, and the dominant term in the second sum is the first term $k = N + 1$. Also the factor $\frac{C_l^\lambda(1)}{h_l^\lambda}$ can be absorbed into A by (6.7). Thus the key in the proof is to estimate

$$(4.16) \qquad \int_{-1}^{1} (1 - \xi^2)^{\lambda - \frac{1}{2}} C_l^\lambda(\xi) \phi_{N+1}(\epsilon \xi + \delta) d\xi.$$

For the Fourier case $\phi_k(x) = e^{2k\pi i x}$, there is an explicit formula for the integral (4.16) in terms of the Bessel function $J_{l+\lambda}(\pi(N+1))$. This, together with detailed estimates on the Bessel function and other asymptotic terms, gives the result (i) in Theorem 4.1 (see [13, 15]). The same formula also helps us in getting the estimate for the Legendre case, by writing the Legendre polynomial as a Fourier series [15]. However, this procedure does not work for the general Gegenbauer case, because of the existence of the weight function. We have thus resorted to finding recursive formulas for (4.16), which allowed us to reduce λ to 0 by changing l and N, hence arriving at an explicit formula which can be analyzed by asymptotics [16]. This procedure gives a less sharp estimate, as indicated before.

The proof for the collocation case is different and uses the analytical assumption (4.3). Details can be found in [17].

We have thus showed that for all the expansions mentioned in the introduction, the truncation error is exponentially small. Thus it is possible to accurately obtain the Gegenbauer expansion coefficients provided $\lambda \sim N$.

4.2. The regularization error. In this subsection we study the regularization error, which is the approximation error of using a finite (first $m+1$ terms) Gegenbauer expansion to approximate an analytic function $f(x)$ in $[-1, 1]$. What makes it different from the usual approximation results is that we require that the exponent λ in the weight function $(1 - x^2)^{\lambda - \frac{1}{2}}$ shall grow linearly with m, the number of terms retained in the Gegenbauer expansion. Thus we have the following problem.

- Given an analytic function $f(x)$ defined on $-1 \leq x \leq 1$, estimate the approximation error in the maximum norm:

$$(4.17) \qquad RE(\lambda, m) = \max_{-1 \leq x \leq 1} \left| f(x) - \sum_{l=0}^{m} \hat{f}^{\lambda}(l) C_l^{\lambda}(x) \right|,$$

  where the Gegenbauer coefficients $\hat{f}^{\lambda}(l)$ are given by (6.10), and $\lambda = \gamma m$ where $\gamma > 0$ is a constant.

We will provide here a proof of the exponential decay of the regularization error, due to Vandeven (private communication). This proof covers more general cases (however, see Remark 4.1 below) than the proof provided in [13].

We first make the following assumption.

Assumption 4.1. There exists a constant $0 \leq r_0 < 1$ and an analytic extension of $f(x)$ onto the elliptic domain

$$(4.18) \qquad D_\rho = \left\{ z : z = \frac{1}{2} \left(re^{i\theta} + \frac{1}{r} e^{-i\theta} \right), \qquad 0 \leq \theta \leq 2\pi, r_0 \leq r \leq 1 \right\}.$$

This assumption is satisfied by all analytic functions defined on $[-1, 1]$. In fact, the smallest r_0 in Assumption 4.1 is characterized by the following property [23]:

$$(4.19) \qquad \overline{\lim_{m \to \infty}} \, (E_m(f))^{\frac{1}{m}} = r_0$$

with $E_m(f)$ defined by

$$(4.20) \qquad E_m(f) = \min_{P \in P_m} \max_{-1 \leq x \leq 1} |f(x) - P(x)|,$$

where P_m is the set of all polynomials of degree at most m.

We start by estimating the Gegenbauer coefficients $\hat{f}^{\lambda}(l)$.

LEMMA 4.1. *The Gegenbauer coefficient $\hat{f}^{\lambda}(l)$, as defined in* (6.10), *can be bounded by*

$$(4.21) \qquad |\hat{f}^{\lambda}(l)| \leq \sqrt{\frac{(l + \lambda)\Gamma(l + 2\lambda)}{\lambda l! \Gamma(2\lambda)}} \frac{1}{C_l^{\lambda}(1)} \max_{-1 \leq x \leq 1} |f(x)|.$$

Proof. Using the definition (6.10) for $\hat{f}^{\lambda}(l)$ and the Cauchy–Schwarz inequality, we get

$$|\hat{f}^{\lambda}(l)| \leq \frac{1}{\sqrt{h_l^{\lambda}}} \sqrt{\int_{-1}^{1} f^2(x)(1 - x^2)^{\lambda - \frac{1}{2}} dx} \leq \sqrt{\frac{h_0^{\lambda}}{h_l^{\lambda}}} \max_{-1 \leq x \leq 1} |f(x)|.$$

Invoking (6.2) and (6.4), we obtain (4.21). □

We are now ready for the following estimate on the regularization error (4.17).

THEOREM 4.2. *If $f(x)$ is an analytic function on $[-1, 1]$ satisfying Assumption 4.1, then for any $r_0 < r < 1$, we have*

$$(4.22) \qquad RE(\lambda, m) \leq Am\sqrt{\frac{m + \lambda}{m}}\sqrt{\frac{(m + 2\lambda)^{m+2\lambda}}{m^m(2\lambda)^{2\lambda}}}r^m.$$

Proof. Using (4.17) and (6.5), we get the very crude estimate

$$RE(\lambda, m) \leq \max_{-1 \leq x \leq 1}|f(x)| + \sum_{l=0}^{m}|\hat{f}^\lambda(l)|C_l^\lambda(1).$$

Using (4.21), we then obtain

$$RE(\lambda, m) \leq \max_{-1 \leq x \leq 1}|f(x)|\left[1 + \sum_{l=0}^{m}\sqrt{\frac{(l + \lambda)\Gamma(l + 2\lambda)}{\lambda l!\Gamma(2\lambda)}}\right]$$

$$\leq \max_{-1 \leq x \leq 1}|f(x)|\left[(m + 1)\sqrt{\frac{(m + \lambda)\Gamma(m + 2\lambda)}{\lambda m!\Gamma(2\lambda)}}\right]$$

$$\leq A \max_{-1 \leq x \leq 1}|f(x)|\left[m\sqrt{\frac{(m + \lambda)(m + 2\lambda)^{m+2\lambda}}{\lambda m^m(2\lambda)^{2\lambda}}}\right],$$

where in the last inequality we have used Stirling's formula (6.6).

Now, we note that in $RE(\lambda, m)$ we can replace f by $f - P$ for any polynomial P with degree at most m. Thus using (4.19) we obtain (4.22). □

From the above estimate we can easily obtain Theorem 4.3.

THEOREM 4.3. *If $\lambda = \gamma m$ where $\gamma > 0$ is a positive constant, then the regularization error defined in (4.17) satisfies*

$$(4.23) \qquad RE(\gamma m, m) \leq Amq^m,$$

where q is given by

$$(4.24) \qquad q = \frac{(1 + 2\gamma)^{\frac{1+2\gamma}{2}}}{(2\gamma)^\gamma}r.$$

Moreover, for γ small enough we have $q < 1$.

Proof. We use (4.22) with $\lambda = \gamma m$ to obtain (4.23). The fact that $q < 1$ for γ small enough is due to the fact that $r < 1$ and

$$\lim_{\gamma \to 0^+}\frac{(1 + 2\gamma)^{\frac{1+2\gamma}{2}}}{(2\gamma)^\gamma} = 1. \qquad □$$

We have the following remarks.

Remark 4.1. If, instead of Assumption 4.1, we assume that $f(x)$ satisfies the assumption that there exist constants $\rho \geq 1$ and $C(\rho)$ such that, for every $k \geq 0$,

$$(4.25) \qquad \max_{-1 \leq x \leq 1}\left|\frac{d^k f}{dx^k}(x)\right| \leq C(\rho)\frac{k!}{\rho^k},$$

then we can prove [13] that the regularization error (4.17) is bounded by

$$(4.26) \qquad RE(\lambda, m) \leq A\frac{C(\rho)\Gamma(\lambda + \frac{1}{2})\Gamma(m + 2\lambda + 1)}{m\sqrt{\lambda}(2\rho)^m\Gamma(2\lambda)\Gamma(m + \lambda)}.$$

Assuming that $\lambda = \gamma m$ for a constant $\gamma > 0$, this becomes

$$(4.27) \qquad RE(\gamma m, m) \le A q^m,$$

where q is given by

$$(4.28) \qquad q = \frac{(1 + 2\gamma)^{1+2\gamma}}{\rho 2^{1+2\gamma} \gamma^\gamma (1 + \gamma)^{1+\gamma}} < 1$$

since $\rho \ge 1$.

As was mentioned in the previous subsection, (4.25) is a standard assumption for analytic functions. ρ is actually the distance from $[-1, 1]$ to the nearest singularity of $f(x)$ in the complex plane. Of course the assumption $\rho \ge 1$ restricts the class of analytic functions to which this estimate can apply. If a function $f(x)$ satisfies both Assumption 4.1 and assumption (4.25) with $\rho \ge 1$, estimate (4.23) may be better or worse than estimate (4.27) depending on the circumstances. To see this, just notice that, roughly speaking, $\frac{1}{2}(r_0 + \frac{1}{r_0}) - 1$ in Assumption 4.1 is equivalent to ρ in (4.25). Thus, we can take, as an example, $\rho = 1$ in (4.25), which corresponds to $r_0 = 2 - \sqrt{3}$ in Assumption 4.1. If $\gamma = 1$, then $q \approx 0.696$ in (4.23) and $q \approx 0.844$ in (4.27); hence, (4.23) is a better estimate in this case. However, if $\gamma = 2.5$, then (4.23) produces a useless estimate $q > 1$, while (4.27) still gives a useful estimate $q \approx 0.920$.

Remark 4.2. If $f(x)$ is analytic not in the whole interval $[-1, 1]$ but in a subinterval $[a, b] \subset [-1, 1]$, we can introduce a change of variable $x = \epsilon\xi + \delta$ with $\epsilon = \frac{b-a}{2}$ and $\delta = \frac{a+b}{2}$ such that $g(\xi) = f(x(\xi))$ is defined and is analytic on $-1 \le \xi \le 1$. The previous estimates will then apply to $g(\xi)$, which can be translated back to the function $f(x)$ with a suitable factor involving ϵ; see [15]. For example, the counterpart of (4.27)–(4.28) is

$$(4.29) \qquad RE(\gamma m, m, \epsilon) \le A q^m$$

with q given by

$$(4.30) \qquad q = \frac{\epsilon(1 + 2\gamma)^{1+2\gamma}}{\rho 2^{1+2\gamma} \gamma^\gamma (1 + \gamma)^{1+\gamma}}.$$

Remark 4.3. If $f(x)$ is not analytic but only C^k, standard analysis [12] gives an $O(\frac{1}{m^k})$ estimate for the regularization error.

4.3. The resolution of the Gibbs phenomenon. We can now combine the results in the previous two subsections to get the following result, which completely removes the side effect of Gibbs phenomenon and gives uniform exponential accuracy for the approximation.

THEOREM 4.4. *Consider an L_1 function $f(x)$ on $[-1, 1]$, which is analytic in a subinterval $[a, b] \subset [-1, 1]$, and satisfies Assumption 4.1, and (4.3) for the collocation case, suitably scaled to $[a, b]$. Assume that either the first $2N + 1$ Fourier coefficients or the first $N + 1$ Gegenbauer coefficients based on the Gegenbauer polynomials $C_k^\mu(x)$, either Galerkin or collocation, are known. Let $\hat{g}_\epsilon^\lambda(l)$, $0 \le l \le m$ be the Gegenbauer expansion coefficients, based on the subinterval $[a, b]$, of the spectral partial sum $f_N(x)$, defined by (4.6) for the Galerkin case and by (4.9) for the collocation case; then for $\lambda = m = \beta\epsilon N$ where $\beta < \frac{2\pi e}{27}$ (Fourier Galerkin case), or $\beta \le \frac{2}{27}$ (general Gegenbauer or spherical harmonic Galerkin case), or $\beta \le 2e/(27(1 + \frac{1}{2\rho}))$ (Fourier or general Gegenbauer collocation case, ρ is defined by (4.3)), we have*

$$(4.31) \qquad \max_{-1 \le \xi \le 1} \left| f(\epsilon\xi + \delta) - \sum_{l=0}^{m} \hat{g}_\epsilon^\lambda(l) C_l^\lambda(\xi) \right| \le A \left(q_T^{\epsilon N} + q_R^{\epsilon N} \right),$$

*where $0 < q_T < 1$ and $0 < q_R < 1$.* □

FIG. 1. *The function $f(x) = x$ (solid line), the Fourier partial sum $f_N(x)$ with $N = 4$ (short dashed line) and $N = 8$ (dotted line), and the approximation through the Gegenbauer procedure using $m = \lambda = N/4$ for $N = 4$ (long dashed line). Reprinted from Journal of Computational and Applied Mathematics, 43/1–2, D. Gottlieb, C.-W. Shu, A. Solomonoff, and H. Vandeven, On the Gibbs phenomenon* I: *Recovering exponential accuracy from the Fourier partial sum of a nonperiodic analytic function, pp. 81–98, 1992 with kind permission from Elsevier Science - NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, The Netherlands.*

We return now to problems outlined in the introduction. Theorem 4.4 answers directly Problems 1 and 3. Problems 4 and 5 can be solved by constructing the trigonometric interpolation polynomial and then applying the procedure outlined above using Theorem 4.4. To solve Problem 6 we construct the interpolation polynomial based on the Gauss (or Gauss–Lobatto) points and then apply the procedure outlined above.

5. Numerical examples. An advantage of the procedure described in the previous section is that it is computationally effective even for small N. There are numerical examples given in, e.g., [13, 14, 16, 17, 31, 7, 34, 35]. Some of the numerical difficulties due to round-off errors are addressed in [34]. We will show three samples in this section to illustrate the theory.

The first is the original Gibbs phenomenon as presented by Michelson in [27]: given the first $2N + 1$ Fourier coefficients of the analytic but nonperiodic function $f(x) = x$, find an approximation to $f(x)$ itself. In Figure 1, taken from [13], we can see that the Fourier series $f_N(x)$ with $N = 4$ and $N = 8$ gives poor approximations throughout the domain and a Gibbs overshoot near the discontinuity. The solution obtained by the Gegenbauer procedure gives excellent results even for the small $N = 4$.

In the second example, we assume that the first $N + 1$ Chebyshev coefficients of

$$f(x) = I_{[-0.5,0.5]}(x) \cdot \sin(\cos(x))$$

are given, where $I_{[-0.5,0.5]}(x)$ is the characteristic function of the interval $[-0.5, 0.5]$, and we try to obtain exponentially accurate point values of $f(x)$ in $[-0.5, 0.5]$. Figure 2, taken from [16], shows the errors (in a logarithm scale) for various N in the interval $[-0.5, 0.5]$. We can clearly see that the errors are uniformly small, even at the discontinuities $x = -0.5$ and $x = 0.5$, and they decay fast with N.

The third example is two dimensional. We assume that the first $2N + 1$ Fourier coefficients of the function $f(x) = e^{i2.3\pi x + i1.2\pi y}$ are given in each of the four quadrants: $-1 \leq x \leq 0, -1 \leq y \leq 0$; $-1 \leq x \leq 0, 0 \leq y \leq 1$; $0 \leq x \leq 1, -1 \leq y \leq 0$; and
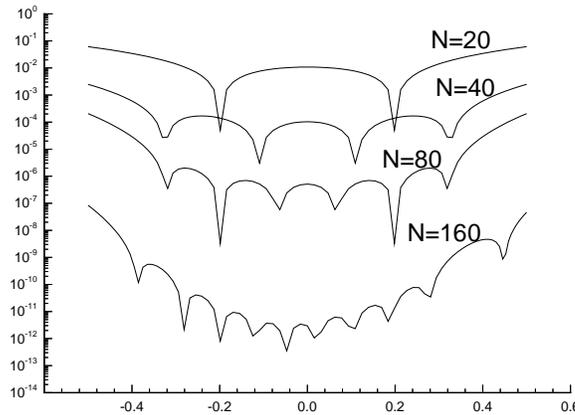

FIG. 2. *Errors in* log *scale, for* $f(x) = I_{[-0.5,0.5]}(x) \cdot \sin(\cos(x))$, *through the Gegenbauer procedure, with* $N = 20, 40, 80, 160$. *Reprinted from D. Gottlieb and C.-W. Shu, On the Gibbs phenomenon* V: *Recovering exponential accuracy in a sub-interval from the Gegenbauer partial sum of a piecewise analytic function, Mathematics of Computation,* 64 (1995), *pp.* 1081–1095 *with permission from the American Mathematical Society.*

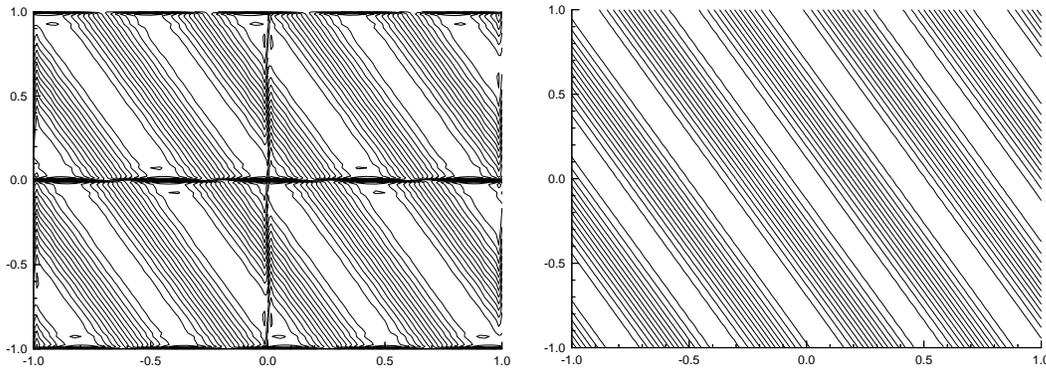

FIG. 3. *Contour plots of* $f(x) = e^{i2.3\pi x + i1.2\pi y}$ *using the Fourier partial sum with* $N = 32$ *in each subdomain. Left, without the Gegenbauer procedure; right, with the Gegenbauer procedure. Reprinted from Computers and Mathematics with Applications, Volume* 33, *A. Gelb and D. Gottlieb, The resolution of the Gibbs phenomenon for 'spliced' functions in one and two dimensions, pp.* 35– 58, 1997, *with kind permission from Elesvier Science Ltd, The Boulevard, Langford Lane, Kidlington* 0X5 1GB, UK.

$0 \leq x \leq 1, 0 \leq y \leq 1$. Since the function is not periodic in any of the quadrants, we clearly see the Gibbs oscillations in Figure 3, left, which is the contour of plot of the Fourier sum for each quadrant with $N = 32$. The application of the Gegenbauer procedure completely removes these oscillations; see Figure 3, right. This example is taken from [8].

6. Appendix. In this appendix we will introduce the Gegenbauer polynomials and discuss their asymptotic behavior. We rely heavily on the standardization in Bateman [1].

DEFINITION 6.1. *The Gegenbauer polynomial* $C_n^\lambda(x)$, *for* $\lambda \geq 0$, *is the polynomial of degree n that satisfies*

$$(6.1) \qquad \int_{-1}^{1} (1 - x^2)^{\lambda - \frac{1}{2}} C_k^\lambda(x) C_n^\lambda(x) dx = 0, \qquad k \neq n$$

and is normalized by

$$(6.2) \qquad C_n^\lambda(1) = \frac{\Gamma(n+2\lambda)}{n!\Gamma(2\lambda)}.$$

The Gegenbauer polynomials thus defined are not orthonormal. In fact, the norm of $C_n^\lambda(x)$ is given by

$$(6.3) \qquad \int_{-1}^{1} (1-x^2)^{\lambda-\frac{1}{2}} \left(C_n^\lambda(x)\right)^2 dx = h_n^\lambda,$$

where

$$(6.4) \qquad h_n^\lambda = \pi^{\frac{1}{2}} C_n^\lambda(1) \frac{\Gamma(\lambda+\frac{1}{2})}{\Gamma(\lambda)(n+\lambda)}.$$

The Gegenbauer polynomials achieve their maximum at the boundary

$$(6.5) \qquad |C_n^\lambda(x)| \le C_n^\lambda(1), \qquad -1 \le x \le 1.$$

In order to study the asymptotics of the Gegenbauer polynomials for large n and λ, we will use heavily the well-known Stirling formula: for any number $x \ge 1$ we have

$$(6.6) \qquad (2\pi)^{\frac{1}{2}} x^{x+\frac{1}{2}} e^{-x} \le \Gamma(x+1) \le (2\pi)^{\frac{1}{2}} x^{x+\frac{1}{2}} e^{-x} e^{\frac{1}{12x}}.$$

The first useful fact is that, for large λ and n, h_n^λ and $C_n^\lambda(1)$ are almost of the same size: there exists a constant A independent of λ and n such that

$$(6.7) \qquad A^{-1} \frac{\lambda^{\frac{1}{2}}}{(n+\lambda)} C_n^\lambda(1) \le h_n^\lambda \le A \frac{\lambda^{\frac{1}{2}}}{(n+\lambda)} C_n^\lambda(1),$$

which is easily provable from (6.4) and the Stirling formula (6.6).

We would also like to quote the Rodrigues formula [1, page 175], which gives an explicit expression for $C_n^\lambda(x)$:

$$(6.8) \qquad (1-x^2)^{\lambda-\frac{1}{2}} C_n^\lambda(x) = G(\lambda, n) \frac{d^n}{dx^n} \left[(1-x^2)^{n+\lambda-\frac{1}{2}}\right],$$

where $G(\lambda, n)$ is given by

$$(6.9) \qquad G(\lambda, n) = \frac{(-1)^n \Gamma(\lambda+\frac{1}{2})\Gamma(n+2\lambda)}{2^n n! \Gamma(2\lambda)\Gamma(n+\lambda+\frac{1}{2})}.$$

Given a function $f(x)$ defined on $[-1, 1]$, its Gegenbauer coefficients $\hat{f}^\lambda(l)$ are defined by

$$(6.10) \qquad \hat{f}^\lambda(l) = \frac{1}{h_l^\lambda} \int_{-1}^{1} (1-x^2)^{\lambda-\frac{1}{2}} f(x) C_l^\lambda(x) dx$$

with h_l^λ given by (6.4), and the Gegenbauer expansion based on the first $m+1$ terms is defined by

$$(6.11) \qquad f_m^\lambda(x) = \sum_{l=0}^{m} \hat{f}^\lambda(l) C_l^\lambda(x).$$

Acknowledgments. We would like to thank Gilbert Strang for many comments on the manuscript and for pointing out that the Vandeven filter (3.32) is essentially the Daubechies filter leading to wavelets. We also thank the American Mathematical Society and the Elsevier Science Publishing Company for giving permission to reproduce the figures.
